We use highly resolved numerical simulations to study turbulent Rayleigh-Bénard convection in a cell with sinusoidally rough upper and lower surfaces in two dimensions for Pr = 1 and Ra = [4 × 10⁶, 3 × 10⁸]. By varying the wavelength λ at a fixed amplitude, we find an optimal wavelength λ_{opt} for which the Nusselt-Rayleigh scaling relation is (Nu = 1 \alpha Ra^{0.483}), maximizing the heat flux. This is consistent with the upper bound of Goluskin and Doering [J. Fluid Mech. 804, 370 (2016)] who proved that Nu can grow no faster than O(Ra^{1/2}) as Ra → \infty, and thus with the concept that roughness facilitates the attainment of the so-called ultimate regime. Our data nearly achieve the largest growth rate permitted by the bound. When \lambda \ll \lambda_{opt} and \lambda \gg \lambda_{opt}, the planar case is recovered, demonstrating how controlling the wall geometry manipulates the interaction between the boundary layers and the core flow. Finally, for each Ra, we choose the maximum Nu among all \lambda, thus optimizing over all \lambda, to find Nu_{opt} = 1.01 × Ra^{0.444}.

The ubiquity and importance of thermal convection in many natural and man-made settings is well known [1–4]. The simplest scenario that has been used to study the fundamental aspects of thermal convection is the Rayleigh-Bénard system [5]. The flow in this system is governed by three nondimensional parameters: (1) the Rayleigh number Ra = \frac{g \alpha \Delta T H^3}{\nu \kappa}, which is the ratio of buoyancy to viscous forces, where g is the acceleration due to gravity, \alpha the thermal expansion coefficient of the fluid, \Delta T the temperature difference across a layer of fluid of depth H, \nu the kinematic viscosity (or momentum diffusivity), and \kappa the thermal diffusivity, (2) the Prandtl number, Pr = \nu/\kappa, and (3) the aspect ratio of the cell, \Gamma, defined as the ratio of its width to height.

The primary aim of the corpus of studies of turbulent Rayleigh-Bénard convection has been to determine the Nusselt number Nu, defined as the ratio of total heat flux to conductive heat flux [Eq. (1)], as a function of the three governing parameters, viz., Nu = Nu(Ra,Pr,\Gamma). For Ra \gg 1 and fixed Pr and \Gamma, this relation is usually sought in the form of a power law: Nu = A(Pr,\Gamma)Ra^\beta, where \beta holds fundamental significance for the mechanisms underlying the transport of heat.

The classical theory of Priestley [6], Malkus [7], and Howard [8] is based on the argument that as Ra → \infty, the dimensional heat flux should become independent of the depth of the cell, resulting in \beta = 1/3. A consequence of this scaling is that the conductive boundary layers (BLs) at the upper and lower surfaces, which are separated by a well-mixed interior, do not interact.

However, Kraichnan [9] reasoned that for extremely large Ra, the BLs undergo a transition leading to the generation of smaller scales near the boundaries that increase the system’s efficiency in transporting the heat, predicting that Nu \sim [Ra/(ln Ra)^{3/2}]. In this, “Kraichnan-Spiegel” or “ultimate regime” (\beta = 1/2), it is argued that the heat flux becomes independent of the molecular properties of the fluid (e.g., [10,11]). Experimental [12–15] and numerical [16–18] studies have found \beta \approx 1/3. Chavanne et al. [19] and He et al. [20] have reported observing transitions to \beta = 0.39 and \beta = 0.38 in their respective experiments, and these findings continue to stimulate discussion [21,22]. Motivated by studies of shear flow, Borue and Orszag [23] used pseudospectral methods at three resolutions (64^3, 128^3, 256^3 and hence, values of Ra) to study “homogeneous” convection in which the BLs are effectively removed. Whilst the highest resolution was not numerically converged, the other two resolutions led to a range of \beta = 0.40 \pm 0.05. This idea was later used in Lattice Boltzmann simulations for Ra = [8.64 × 10^6, 1.38 × 10^7] to find \beta = 0.51 \pm 0.06 [24], ascribing this to the ultimate regime.

Recently, Waleffe et al. [25] and Sondak et al. [26] numerically computed the steady solutions to the Oberbeck-Boussinesq equations for Ra ≤ 10^9 and 1 ≤ Pr ≤ 100 in two dimensions. By fixing Ra and Pr, steady solutions for different horizontal wave numbers \alpha were computed. The solution that maximized heat transport, Nu = Nu_{opt}, was called optimal, for which \alpha = \alpha_{opt} and Nu_{opt} = 0.115 × Ra^{0.31}, which is in agreement with experiments [12]. Although they found that \beta was independent of Pr, the Prandtl number did have considerable effect on the geometry of the coherent structures that transported heat. For Pr > 7, the scaling for the optimal wave number was found to be \alpha_{opt} = 0.257 × Ra^{0.256}. The horizontally averaged optimal temperature profiles had the
following features: (a) the BLs were always unstably stratified. (b) The core region was either stably (Pr \leq 7) or unstably (Pr > 7) stratified. (c) The transition regions between the core and BLs were always stably stratified. Thus, with small departures, these profiles correspond to the marginally stable profile of Malkus [7], with β = 1/3. 

An important aspect emerging from the study of planar Rayleigh-Bénard convection in two dimensions for Pr \geq 1 is that the flow field [27] and the Nu-Ra scaling relations [25,26,28] are similar to those in three dimensions. Thus, this correspondence permits one to understand the processes driving the heat transport using well-resolved two-dimensional simulations.

It is clear that the value β takes in the limit Ra \rightarrow \infty depends on the interaction between the BLs and the core flow. To understand the role of BLs in thermal convection, Shen et al. [29] introduced rough upper and lower surfaces made of pyramidal elements in a cylindrical cell. They found that these elements enhanced the production of plumes, which were directly injected into the core flow, leading to an increase in Nu. The increase in Nu was due to an increase in the prefactor in the Nu scaling relation. Whereas subsequent experiments found no effect of periodic roughness on β [30–32], later studies confirmed that the changes in the flow field brought about by surface roughness depends on the interaction between the BLs and the core flow. As summarized by Ahlers [41], it was first noted by Niemela & Sreenivasan [13] state that “More work is needed to resolve this issue”. Here, we present results from highly-resolved numerical simulations of Rayleigh-Bénard convection in a cell with rough upper and lower surfaces in two dimensions. The roughness profiles chosen are sinusoidal. By keeping the amplitude fixed and varying the wavelength of the rough surfaces, we systematically study their effects on the heat transport.

The geometry and the dimensionless equations of motion studied here are shown in Fig. 1. The aspect ratio of the cell, \( \Gamma \equiv L_x/L_z \), is fixed at 2. The rough surfaces have a wavelength \( \lambda \equiv \lambda^* \) and an amplitude \( h \equiv h^*/L_z \). The equations of motion for thermal convection are the Oberbeck-Boussinesq (O-B) equations [5], and are non-dimensionalized by choosing \( H = L_z \), 2h as the length scale and \( U_0 = \sqrt{g\alpha\Delta T}H \) as the velocity scale. Hence, the time scale is \( t_0 = H/U_0 \). Here, \( u(x,t) = (u(x,t), w(x,t)) \) is the velocity field, \( T(x,t) \) is the temperature field, \( k \) is the unit vector along the vertical, and \( p(x,t) \) is the pressure field. No-slip and Dirichlet conditions for \( u \) and \( T \) are imposed on the rough surfaces, and periodic conditions are used in the horizontal direction.

The O-B equations were solved using the Lattice Boltzmann method with separate distributions for the momentum and temperature fields [42–46]. Our code has been extensively tested against results from numerical simulations for a wide range of different flows, and the details of the validation can be found in [40,47].

For each of ten \( \lambda^* \)'s (see Fig. 2), we simulated over the range \( Ra = [4 \times 10^5, 3 \times 10^8] \). The planar wall case is \( \lambda = 0 \), and the amplitude of the roughness is fixed at \( h = 0.1 \) and Pr = 1 for all simulations. We ran the simulations for at least 143t_0, where \( t_0 \) is the turnover time, and statistics were collected only after 100t_0. The Nusselt number was computed as

\[
Nu = \frac{\left[ -k \frac{\partial T}{\partial z} + wT \right]_{z=z_c}}{k\Delta T/H},
\]

where the overbar represents the horizontal and temporal averages. We should note here that this definition of Nu, in
general, does not reduce to unity in the static case for arbitrary roughness geometries [1]; however, for the sinusoidal geometries used here, this choice gives $\lambda \approx 1$ when $Ra = 0$. To give an example of the spatial resolutions in the simulations, for $\lambda = 1$ and $Ra = 2 \times 10^9$, the number of grid points used are $N_x = 2800$ and $N_z = 1400$. Grid independence was ascertained from simulations at $Ra = 2 \times 10^9$ for $\lambda = 0.03$ and 0.2 using two grids: (a) $N_x = 2400$, $N_z = 1200$ and (b) $N_x = 2000$, $N_z = 1000$. The difference between Nu computed at $z_e = L_z/2$ for the two grids was less than 1.2%. As an additional check, Nu was computed at three different depths $z_e = L_z/4, L_z/2$, and $3L_z/4$; and the difference between Nu at any two depths was less than 0.5%. More simulation details are provided in the Supplemental Material [48].

For each $\lambda$, we obtained $\beta$ from a linear least-squares fit to the Nu(Ra) simulation data. Figure 2 shows $\beta$ in the scaling relation $Nu - 1 = A \times Ra^\beta$ as a function of $\lambda$. At the optimal wavelength $\lambda_{opt} = 0.1$, $\beta$ attains a maximum value of 0.483, which indicates that the influence of BLs on heat transport has been minimized. It is clear that in the limits $\lambda \ll \lambda_{opt}$ and $\lambda \gg \lambda_{opt}$, the planar case is approached. The Nu-Ra scaling relations for different $\lambda$ are shown in Fig. 3. The linear least-squares fit for $\lambda_{opt} = 0.1$, giving $Nu - 1 = 0.0042 \times Ra^{0.483}$, is shown in Fig. 3(a). The roughness elements are “submerged” inside the thermal BLs for $Ra < 10^8$ (not shown), and hence, as seen in Fig. 3(b), the values of Nu for these Ra are close to those for larger $\lambda$. The increase in $\beta$ for $\lambda = 0.1$, relative to other $\lambda$, is clear from Fig. 3(b). Figure 3(b) also shows the fit for $Nu_{opt}(Ra)$, which is obtained in the following manner: for each Ra, we choose the maximum Nu among all $\lambda$, effectively optimizing over all $\lambda$. These data are described by $Nu_{opt} - 1 = 0.01 \times Ra^{0.444}$.

The flow field for the case of $\lambda_{opt} = 0.1$ and $Ra = 2 \times 10^9$ is shown in Fig. 4 where the following features are apparent: 1. Two large convection rolls in the cell interior. 2. The “unstable” BLs at the upper and lower surfaces. 3. The production of plumes from the fluid moving along the rough surfaces and their ejection from the tips of the roughness elements. By varying $\lambda$, we have achieved a state in which the interaction between the core flow and the BLs over the roughness elements has been enhanced. This results in an unstable state for the BLs, which then leads to the generation and ejection of plumes from the roughness tips. As noted above, in the case of a single rough wall,
maximum value of $\beta$ was found to be $\beta \approx 0.36$ [40], but at a slightly larger $\lambda$. This highlights the role played by the second rough wall in further decreasing the role of the BLs in transporting heat. We should note here that in spite of the differences in geometry, our results have a correspondence with those of Waleffe et al. [25] and Sondak et al. [26] in that there is a length scale in each setting ($\lambda_{\text{opt}}$ in ours and $2\pi/\alpha_{\text{opt}}$ in theirs) that optimizes heat transport. The optimization occurs through the manipulation of the coherent structures that transport heat, though in detail it is accomplished in different ways.

Our results are consistent with those of Goluskin & Doering [1], who used the background method to compute upper bounds [49] on Nu for R-B convection in a domain with rough upper and lower surfaces that have square-integrable gradients. They prove that $\text{Nu} \leq C R a^{1/2}$, where $C$ depends on the geometry of roughness. Our results show that for the optimal wavelength, the heat transport is $\text{Nu} = 0.0042 \times R a^{0.483}$, with the value of $C$ being four orders of magnitude larger than ours, but with an exponent approaching their result. Importantly, their approach provides a key framework for exploring a range of amplitudes and wavelengths using our methodology. Indeed, by varying both amplitude and wavelength over a significant range, the systematic effects of the BLs, and thus, the molecular properties of the fluid, may be realized, comparing and contrasting the concept of a laminar-to-turbulent BL transition, with the enhanced forcing associated with unstable BL’s triggered by the roughness as seen here.
